How/When QSOs Turn on

Galaxy Mergers (e.g., Mihos & Hernquist 1996)

Can occur during two phases

a) After First Passage

Tidal torques \rightarrow Bar Formation \rightarrow Gaseous Inflow

How/When QSOs Turn on

Galaxy Mergers (e.g., Mihos & Hernquist 1996)

Can occur during two phases

a) After First Passage

b) During Final Coalescence

Secular Process: i.e. “Non-Merging”

a) Recycled gas

(Ciotti & Ostriker 2007)

b) Wild Disk Instabilities

(Bournaud+2011)

How/When QSOs Turn on

Galaxy Mergers (e.g., Mihos & Hernquist 1996)

Two Phases

First Passage

Final Coalescence

e. "Non-Merging"

- a) Recycled gas (Ciotti & Ostriker 2007)
- b) Wild Disk Instabilities (Bournaud+2011)

Single Galaxy

First Passage Quasar

- A quasar that has been triggered during the first passage of a merger event
- Expect a companion galaxy at ~ 50 kpc with comparable mass to quasar host
- Companion galaxy does not necessarily have to be a quasar as well

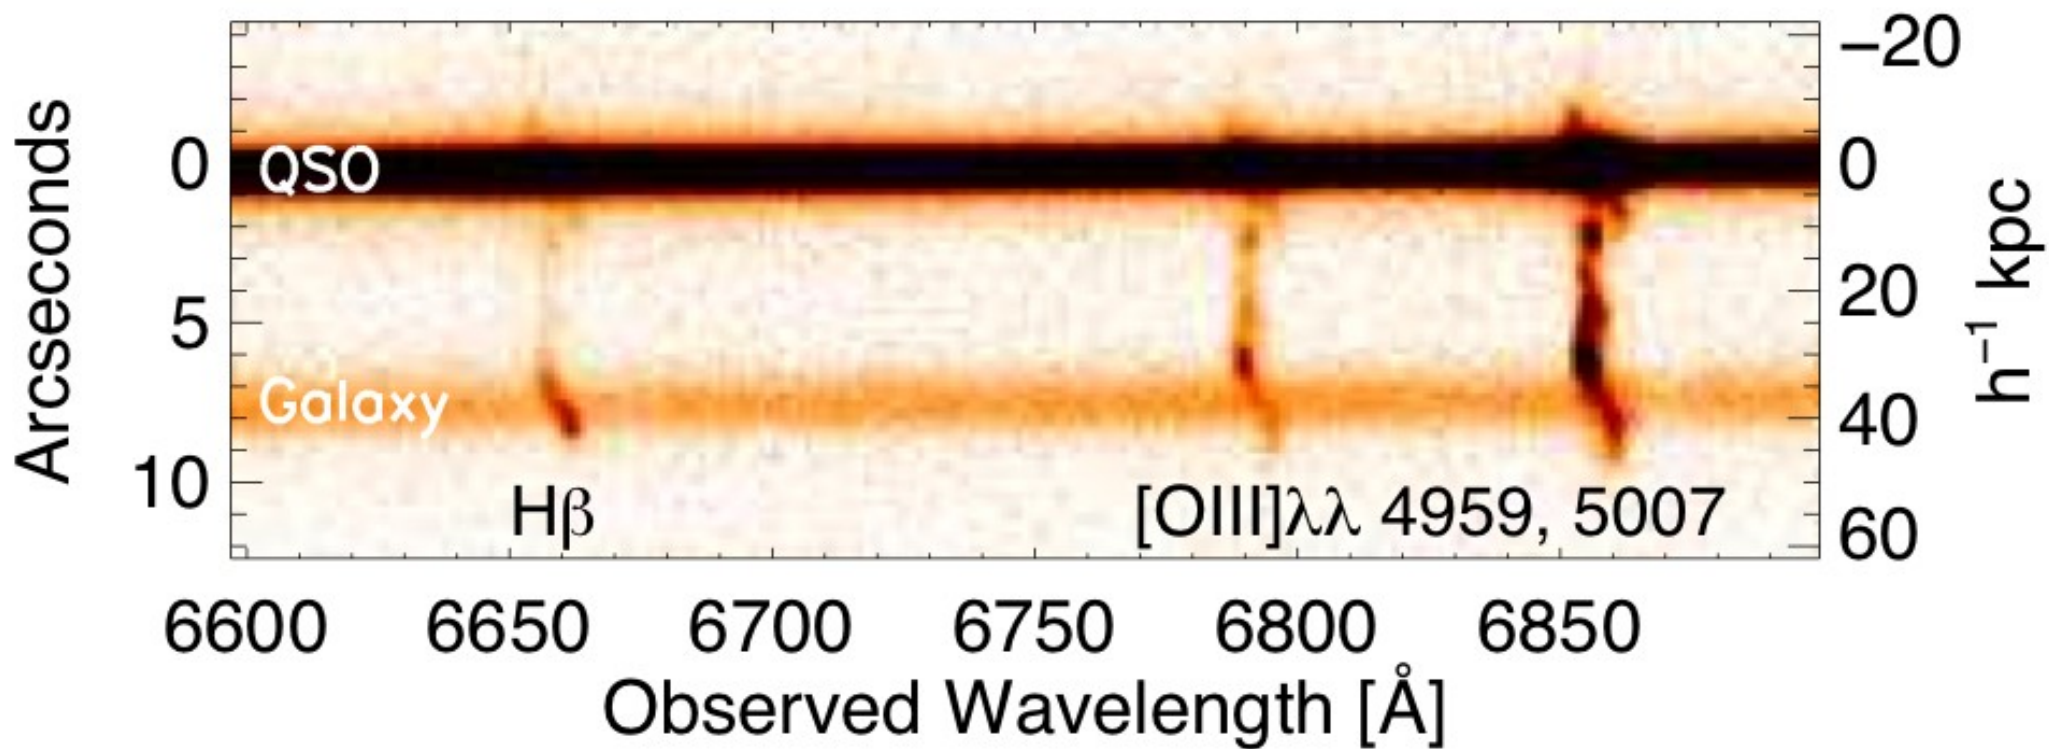

$z = 0.369$ quasar

$z = 0.3693$

$\Delta v = 159 \pm 20 \text{ km/s}$

$b = 38 \text{ kpc}$

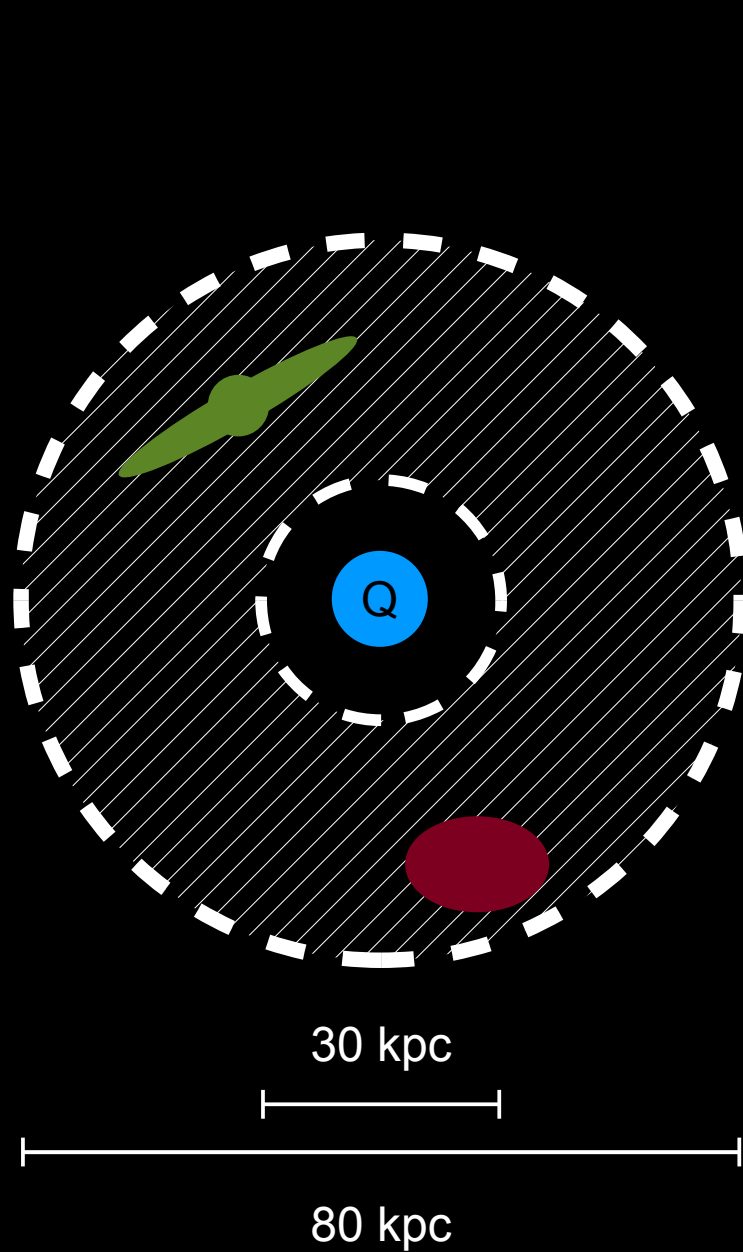

- QSO photoionizing a bridge of material connecting the two galaxies

- Separation & kinematics consistent with a first passage merger

- Inferred companion galaxy SFH is consistent with a burst triggered during first passage of interaction

$$\Delta z < 3\sigma_z$$

Completeness Limit = 1:8

Ingredients

- Need a catalog of quasars where we have large numbers at distances where we can expect to see companions
 - $z < 0.2$ quasars from Schneider+2010 catalog
- Want photometric redshifts and stellar masses of companion galaxies
 - obtainable from SDSS photometry
- Want mass of quasar host galaxy
 - use SMBH mass estimated by Shen+2010 combined with Magorrian Relation

Interlopers

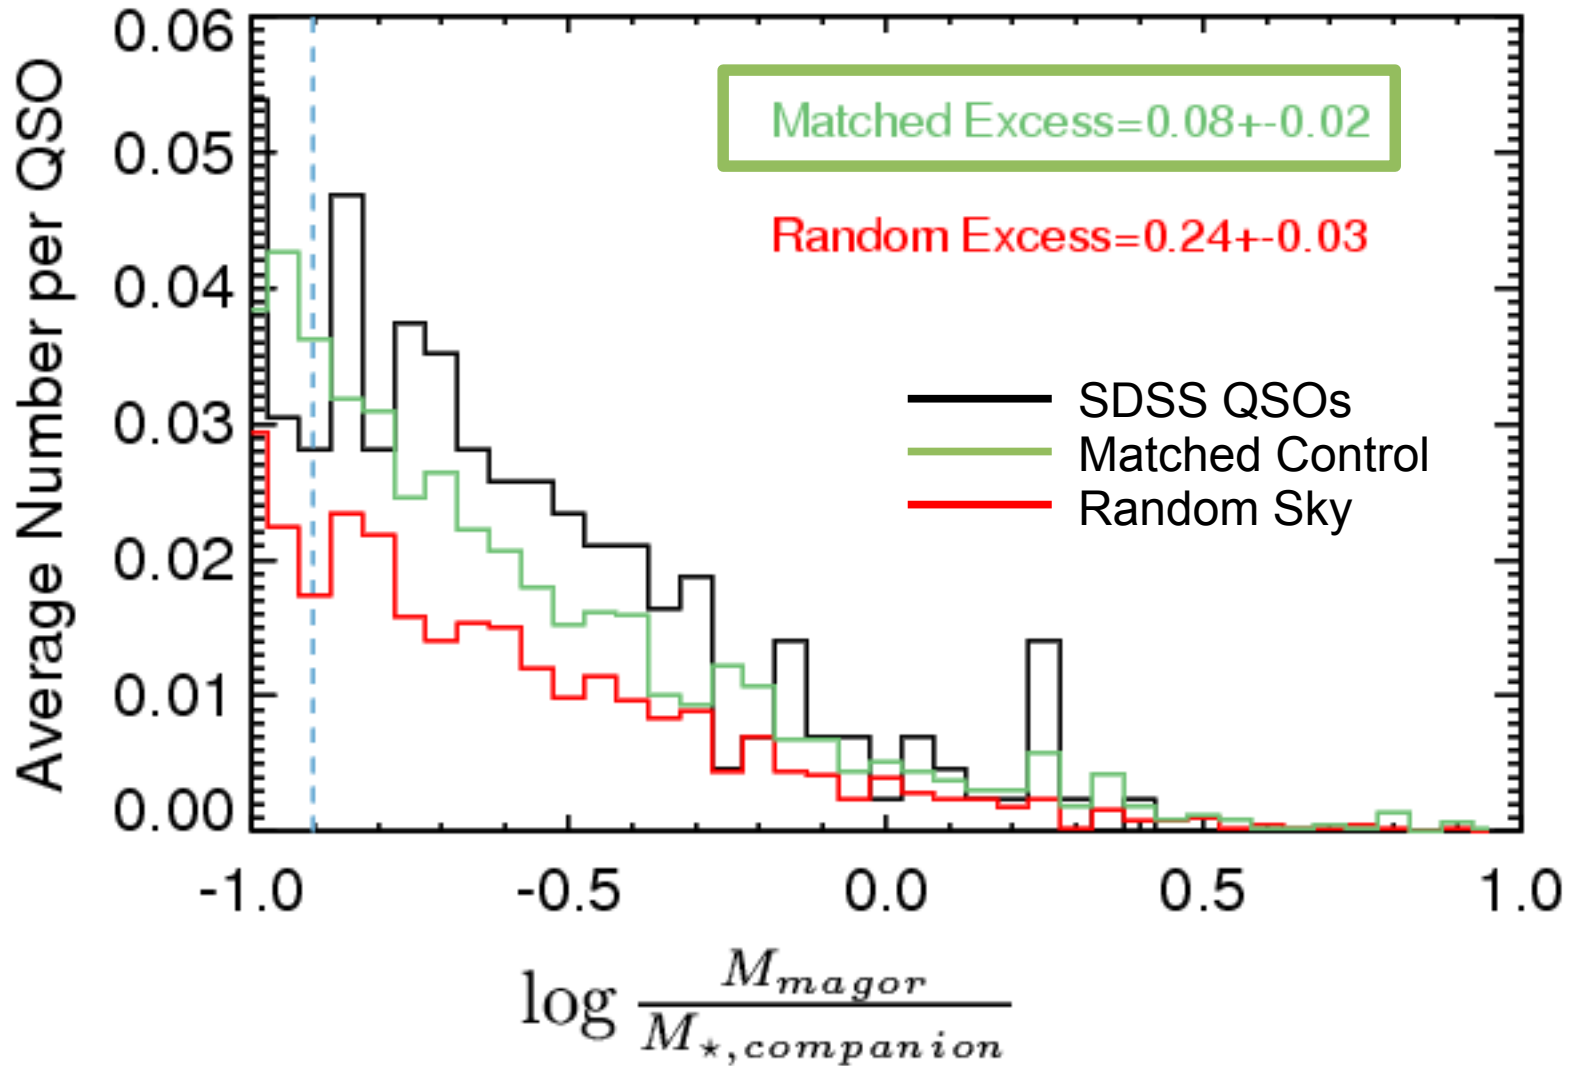

- Generous cut in photometric redshift ($\Delta z < 3\sigma_z$) results in a large number of interlopers meeting our criteria
- So we need to compare with a set of control fields to subtract the background

Perform the same experiment on two sets of control fields:

- 1.) Empty Sky
- 2.) Mass-matched Control Sample
 - Magorrian Mass is (M_{magor}) not an ideal proxy for stellar mass
 - compare luminosity functions at distance between 1–1.2 Mpc
 - **Find a factor of 2 correction**

Detected Excess

$$\Delta z < 3\sigma_z$$

Mass Ratio

Quasar Triggering Toy Model

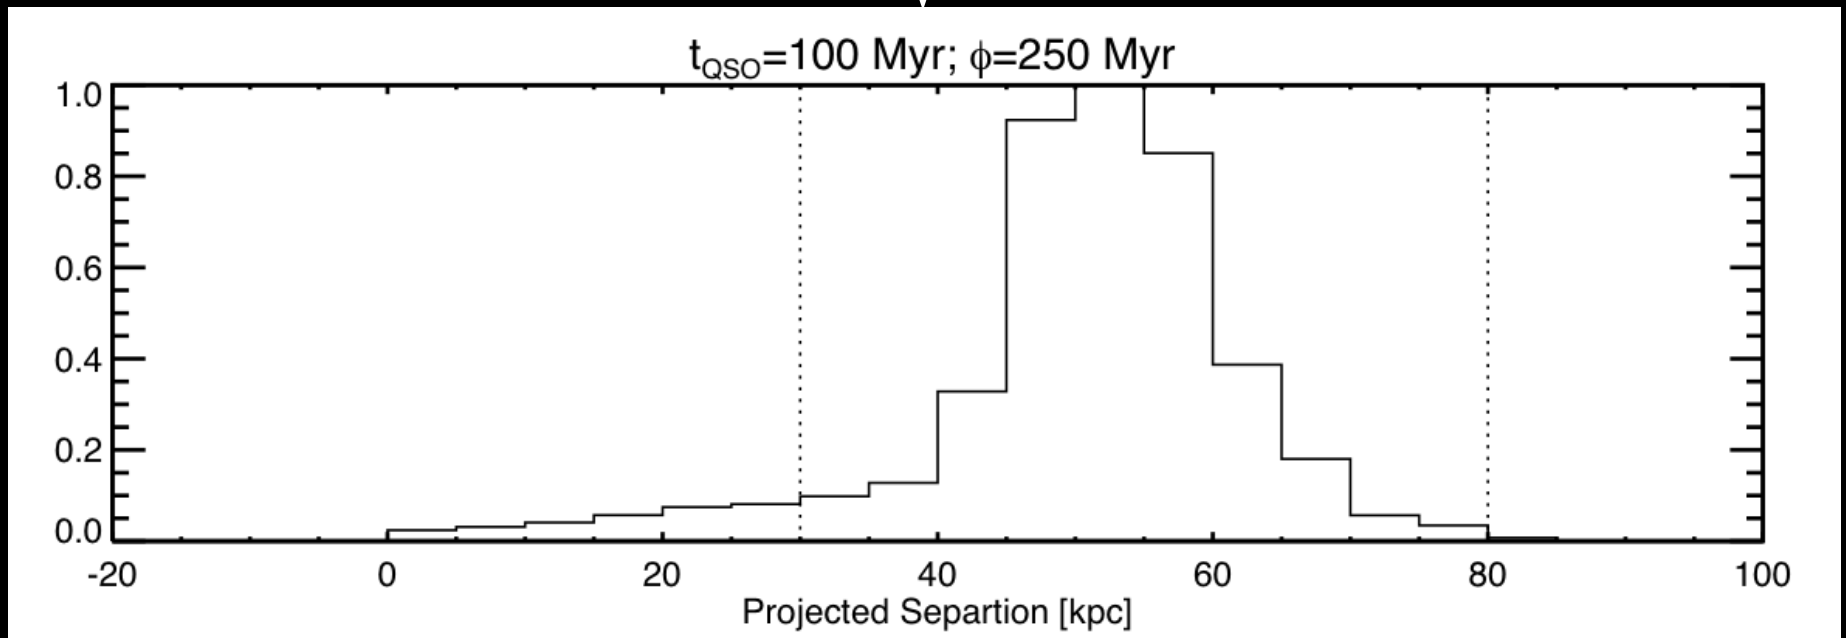

Completeness Correction

Cosmological Orbit Distribution
(e.g. Wetzel+2010)

Parameterize a Model for QSO Triggering
 t_{QSO} ϕ_{lag}

GalMer: Galaxy Merger
Simulation Database

$$t_{qso} = 10 \text{ Myr}$$

$$\phi_{lag} = 250 \text{ Myr}$$

Constraining Triggering Parameters

- Assume a fraction of quasars triggered during first passage \rightarrow infer triggering properties

Future Work

- Study interacting pairs where one galaxy is in a quasar phase
 - Awaiting HST data from successful proposal to study morphologies of galaxies in same merger stage
 - Try to answer the question of why one quasar is on and the other is not
 - Comparison of SMBH and galaxy masses at this intermediate stage will provide insights on evolution along the Magorrian relation
- Search for more pairs with quasar photoionized extended tidal features
 - study quasar lifetime, isotropy, and triggering

Summary

- Statistical study performed studying companions near $z < 0.2$ SDSS QSOs to determine which fraction of quasars are triggered during the first passage stage of a merger
- Determined a significant excess ($> 8 \pm 2$ %) companions with mass ratio $> 1:8$ near quasars (30-80 kpc) interpreted as galaxies interacting with quasar hosts
- Used simulations to estimate a completion correction which increases fraction to $\sim 20\%$

Open Questions

- What is the dominant triggering mechanism of quasars?
- What does this teach us about SMBHs and their effect on galaxy evolution?
- What are the key parameters that determine why in these pairs one galaxy is in a quasar phase and the other is not?

Thank You
